Summary

Background Tracheal intubation is common in the care of critically ill adults and is frequently complicated by hypotension, cardiac arrest, or death. We aimed to evaluate administration of an intravenous fluid bolus to prevent cardiovascular collapse during intubation of critically ill adults.

Methods We did a pragmatic, multicentre, unblinded, randomised trial in nine sites (eight ICUs and one emergency department) around the USA. Critically ill adults (≥ 18 years) undergoing tracheal intubation were randomly assigned (1:1, block sizes of 2, 4, and 6, stratified by study site) to either an intravenous infusion of 500 mL of crystalloid solution or no fluid bolus. The primary outcome, assessed in the intention-to-treat population, was cardiovascular collapse, defined as a new systolic blood pressure <65 mm Hg; new or increased vasopressor receipt between induction and 2 min after tracheal intubation; or cardiac arrest or death within 1 h of tracheal intubation. Adverse events were assessed in the as-treated population. This trial, which is now complete, is registered with ClinicalTrials.gov, number NCT03026777.

Findings Patients were enrolled from Feb 6, 2017, to Jan 9, 2018, when the data and safety monitoring board stopped the trial on the basis of futility. By trial termination, 337 (63%) of 537 screened adults had been randomly assigned. Cardiovascular collapse occurred in 33 (20%) of 168 patients in the fluid bolus group compared with 31 (18%) of 169 patients in the no fluid bolus group (absolute difference 1.3% [95% CI -7.1% to 9.7%]; $p=0.76$). The individual components of the cardiovascular collapse composite outcome did not differ between groups (new systolic blood pressure <65 mm Hg 11 [7%] in the bolus group vs ten [6%] in the no-bolus group, new or increased vasopressor 32 [19%] vs 31 [18%], cardiac arrest within 1 h seven [4%] vs two [1%], death within 1 h of intubation two [1%] vs one [1%]). In-hospital mortality was not significantly different in the fluid bolus group (48 [29%]) compared with no fluid bolus (59 [35%]).

Interpretation Administration of an intravenous fluid bolus did not decrease the overall incidence of cardiovascular collapse during tracheal intubation of critically ill adults compared with no fluid bolus in this trial.

Introduction

Millions of critically ill adults undergo tracheal intubation each year.^{1,2} As many as one in four critically ill adults undergoing tracheal intubation have cardiovascular collapse—defined as shock, cardiac arrest, or death during or immediately following the procedure.^{3,4} Peri-intubation cardiovascular collapse is associated with a significant increase in the risk of mortality.^{5,6}

The administration of an intravenous fluid bolus beginning before induction of anaesthesia has been proposed as a way to prevent cardiovascular collapse during tracheal intubation in the intensive care unit (ICU).^{3,4,7-9} In one observational study,³ implementation of a ten-item pre-intubation checklist, which included pre-induction fluid bolus administration in patients without cardiogenic pulmonary oedema, was associated with a decreased incidence of cardiovascular collapse. No randomised trials have examined the effect of fluid bolus

administration on outcomes of tracheal intubation. In addition to the hypothesised beneficial effects on peri-intubation haemodynamics, fluid bolus administration among critically ill adults might incur immediate^{10,11} and delayed risks.¹²⁻¹⁴ In clinical practice, approximately half of critically ill adults undergoing tracheal intubation receive fluid bolus administration in North America and Europe.^{3,15,16}

In this pragmatic, multicentre, randomised trial, we aimed to test the hypothesis that the administration of an intravenous fluid bolus would reduce the incidence of cardiovascular collapse compared with no fluid bolus.

Research in context

Evidence before this study

Tracheal intubation is common in the care of critically ill patients. As many as 25% of critically ill adults have cardiovascular collapse during the intubation procedure. Cardiovascular collapse during intubation is attributed to three potential mechanisms, all of which might respond to increasing preload via intravenous fluid administration: hypotension associated with common induction medications, increased venous capacitance from decreased circulating catecholamines, and decreased venous return secondary to positive pressure applied to the thoracic cavity. Administration of an intravenous fluid bolus to prevent cardiovascular collapse has been studied indirectly in one observational study of a pre-intubation checklist, which included both pre-induction fluid bolus and positive pressure ventilation. Use of the checklist was associated with an 11% absolute reduction in the incidence of cardiovascular collapse. The PrePARE trial, the results of which are reported here, was a pragmatic, multicentre, unblinded, randomised, controlled trial in nine sites across the USA in which critically ill adults undergoing tracheal intubation were randomly assigned 1:1 to an intravenous infusion of 500 mL of crystalloid solution beginning before induction versus no fluid bolus. Trial design began with a search of PubMed and ClinicalTrials.gov from inception to Nov 14, 2016. This search was repeated before the interim analysis done by the Data Safety and Monitoring Board. Evidence from the PreVent trial was not published prior to the start of the PrePARE trial. PreVent and PrePARE started simultaneously and PrePARE finished prior to PreVent finishing.

Added value of this study

The PrePARE trial is, to our knowledge, the only randomised trial examining the effect of intravenous fluid bolus administration to prevent cardiovascular collapse among critically ill adults undergoing tracheal intubation. Fluid bolus administration did not decrease the overall incidence of cardiovascular collapse compared with no fluid bolus administration. Positive pressure ventilation modified the effect of fluid bolus administration on cardiovascular collapse. Fluid bolus administration appeared to decrease the risk of cardiovascular collapse among patients receiving pre-intubation positive pressure ventilation and appeared to increase the risk of cardiovascular collapse among patients not receiving pre-intubation positive pressure ventilation.

Implications of all the available evidence

Among all critically ill adults undergoing tracheal intubation, the existing evidence does not support administration of a fluid bolus beginning before induction to prevent the common complication of cardiovascular collapse. The results of the PrePARE and PreVent trials together suggest that an intubation strategy involving fluid bolus administration without pre-intubation positive pressure ventilation should not be routine care. Whether fluid bolus administration prevents cardiovascular collapse among patients who receive positive pressure ventilation before intubation should be the focus of future research.

intubation (PrePARE) trial was a pragmatic, multicentre, unblinded, randomised trial comparing administration of a fluid bolus beginning before induction with no fluid bolus administration during tracheal intubation of critically ill adults. At seven of the nine study sites, co-enrolment could occur in an independent randomised trial comparing prophylactic bag-mask ventilation (BMV) with no prophylactic ventilation during tracheal intubation (PreVent Trial), the results of which have been previously reported.¹⁷ Patients enrolled in PrePARE and not co-enrolled in PreVent were excluded from PreVent on the basis of the bedside clinician's evaluation of the PreVent exclusion criteria. The protocol was approved at all sites by either a local or central Institutional Review Board with a waiver of informed consent. The statistical analysis plan was published online before completion of enrolment, and the trial protocol has also been published at this site.

Eligible critically ill patients (aged ≥ 18 years) undergoing tracheal intubation in the nine participating study sites were enrolled.

Study sites comprised six medical ICUs, one trauma ICU, one neurological ICU, and one emergency department at tertiary-care medical centres across the USA (appendix p 9). Patients were excluded if awake

intubation was planned, if intubation was required too immediately to permit randomisation, if treating clinicians felt administration of a fluid bolus was required or contraindicated for the optimal care of the patient, or if patients were prisoners or pregnant.

Randomisation and masking

Patients were randomly assigned in a 1:1 ratio to fluid bolus or no fluid bolus administration in permuted blocks of two, four, and six, stratified by study site. A study investigator (MWS) generated the allocation sequence using Sealed Envelope randomisation after which group assignment was concealed in opaque envelopes at each study site until after the decision had been made by the treating team to enrol a patient in the trial. Owing to the nature of the intervention, patients, clinicians, and study staff were aware of study group assignment after randomisation.

Procedures

For patients assigned to the fluid bolus group, the treating team initiated intravenous administration of 500 mL of crystalloid solution before induction of anaesthesia.

The study protocol recommended the fluid bolus be placed above the level of the intravenous access, infused

For the statistical analysis plan
see [https://rocket.app.vumc.org/
index.php?doc_id=20364](https://rocket.app.vumc.org/index.php?doc_id=20364)

by both gravity and bag pressure, and infused to completion of 500 mL through induction and laryngoscopy (appendix p 3).

For patients randomly assigned to the no fluid bolus group, the study protocol recommended against the administration of any new crystalloid solutions between enrolment and 2 min after completion of tracheal intubation. Intravenous fluid administration initiated as a part of clinical care before enrolment was continued in either study group.

With the exception of patients also enrolled in the PreVent trial of bag mask ventilation,¹⁷ all aspects of the intubation procedure were at the discretion of the clinical team.

Periprocedural endpoints were collected by independent observers (ICU providers trained in the definitions of each outcome) who were present in the patient's room but did not participate in the procedure. To confirm the accuracy of the data collected by the independent observers, the primary investigators concurrently assessed the same endpoints in a non-random convenience sample of study intubations.

Outcomes

The composite primary outcome of cardiovascular collapse consisted of the following components: systolic blood pressure newly less than 65 mm Hg between induction and 2 min after tracheal intubation; new or increased vasopressor use between induction and 2 min after tracheal intubation; cardiac arrest within 1 h of tracheal intubation; or death within 1 h of tracheal intubation.^{3,4,18} Secondary outcomes included each individual component of the composite primary outcome; any additional fluids given to either group, started between induction and 2 min after tracheal intubation; lowest systolic blood pressure between induction and 2 min after tracheal intubation; change in systolic blood pressure from induction to lowest systolic blood pressure; number of laryngoscopy attempts required for intubation; number of ventilator-free days; number of ICU-free days; and in-hospital mortality over a 28 day follow-up period. A full list of outcomes is provided in the appendix (p 6). Safety outcomes were lowest oxygen saturation, highest fraction of inspired oxygen, and highest positive end-expiratory pressure in the 24 h after intubation; cumulative diuretic dose (in furosemide equivalents) on the day of enrolment and from enrolment to 3 days after enrolment; and cumulative intravenous fluid administration from enrolment to 3 days after enrolment.

Statistical analysis

On the basis of previous research,¹⁹ we anticipated a 15% incidence of cardiovascular collapse in the fluid bolus group and 25% in the no fluid bolus group. To detect this relative risk reduction of 40%, we planned to enrol a total of 500 patients to provide 80% statistical power with a two-sided alpha level of 0.05. A single, planned interim analysis was done by the Data and Safety

Monitoring Board (DSMB) with complete data from the first 250 patients using pre-specified stopping rules for efficacy, safety, and futility (appendix p 7).

The primary analysis was an unadjusted, intention-to-treat comparison of the proportions of patients in each study group who had the primary outcome by means of a χ^2 test. Prespecified secondary analyses included evaluation for heterogeneity of treatment effect by baseline co-variables, such as random assignment to BMV for patients co-enrolled in the PreVent trial, by means of formal tests of interaction in a logistic regression model. The complete prespecified statistical analysis plan is available in the appendix (p 5). Analyses were done by means of IBM SPSS Statistics (version 23.0) or Stata (version 15.1). This trial is registered with ClinicalTrials.gov, number NCT03026777.

Role of the funding source

The funders had no role in conception, design, or conduct of the study; collection, management, analysis, interpretation, or presentation of the data; or preparation, review, or approval of the manuscript. DRJ, JDC, MWS, and TWR had access to the raw data; the corresponding author had full access to all of the data and the final responsibility to submit for publication.

Results

Eligible patients were enrolled from Feb 6, 2017, through to Jan 9, 2018, when the DSMB stopped the trial on the basis of prespecified futility stopping criteria at the single, planned interim analysis of complete data from the first 250 patients enrolled. Details of the interim stopping analyses can be found in the appendix (p 7).

Of 537 critically ill adults intubated at the nine sites between beginning enrolment and notification of trial termination by the DSMB, 511 met the inclusion criteria and 337 (63%) were enrolled and randomly assigned to either the fluid bolus group (n=168) or the no fluid bolus group (n=169; figure 1; table 1; appendix p 11).

Post-randomisation procedural characteristics did not differ between groups, including in choice or dose of sedative and neuromuscular blocking procedural medications (appendix p 12).

Among 168 patients assigned to the fluid bolus group, 165 patients (98%) received the full 500 mL fluid bolus and three patients (2%) did not receive a fluid bolus. Among 169 patients assigned to the no fluid bolus group, two patients (1%) received a fluid bolus and 167 patients (99%) did not receive a fluid bolus (figure 1). To assess for the separation between study groups regarding the volume of fluid delivered before induction of anaesthesia, we used a convenience sample of 38 patients (11%) in which the volume of fluid infused before induction was directly observed by a study investigator. The median volume of crystalloid infused before induction was 200 mL (IQR 200–325; mean 262 mL, SD [119]) in the fluid bolus group and 0 mL (IQR 0–0, $p < 0.0001$) in the

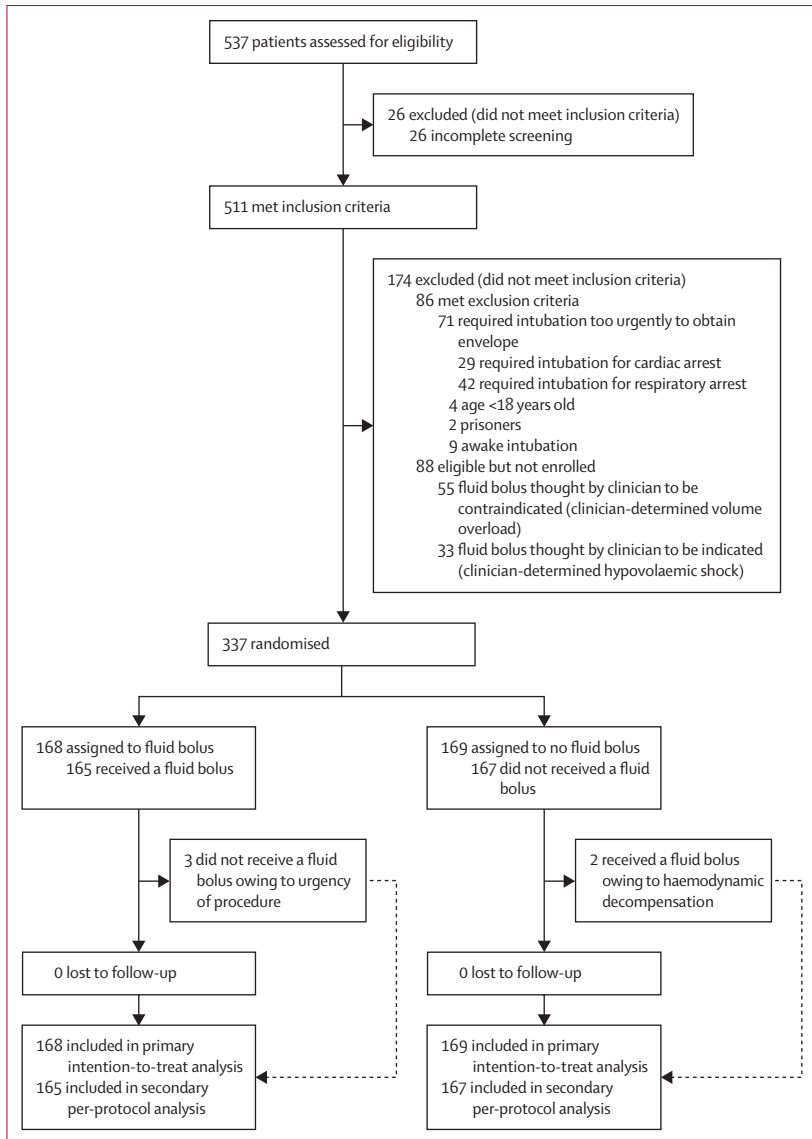

Figure 1: Trial profile

no fluid bolus group. In the same convenience sample, the primary outcome was also observed by a study investigator. Agreement regarding a systolic blood pressure of less than 65 mm Hg, need for new or increased vasopressors, or cardiac arrest or death within 1 h of intubation was 100% between the independent observer and the study investigator.

The primary outcome of cardiovascular collapse occurred in 33 (20%) of 168 patients in the fluid bolus group compared with 31 (18%) of 169 patients in the no fluid bolus group (absolute difference 1.3% [95% CI -7.1 to 9.7], $p=0.76$; figure 2).

The incidence of each component of the composite outcome did not differ significantly between groups (table 2). Results were similar in prespecified analyses

Table 1: Baseline characteristics

adjusting for age, severity of illness, receipt of vasopressors before enrolment, and lowest systolic blood pressure before enrolment (appendix p 13). In a prespecified, per-protocol analysis of the 332 patients who received the intervention to which they were assigned, the incidence of cardiovascular collapse did not differ between groups (appendix p 17).

Administration of a fluid bolus did not significantly affect any of the prespecified secondary outcomes (table 2; appendix p 14) or safety outcomes (table 3). In the overall study population regardless of randomisation assignment, occurrence of cardiovascular collapse was significantly associated with decreased ICU-free days, ventilator-free days, and survival (table 4).

Analyses of heterogeneity of treatment effect are presented in figure 3 and the appendix p 16. The use of non-invasive positive pressure ventilation for pre-oxygenation ($p_{\text{interaction}}=0.032$) and BMV between induction and laryngoscopy ($p_{\text{interaction}}=0.0080$) significantly modified the effect of fluid bolus administration on cardiovascular collapse. For patients receiving positive pressure ventilation, either by non-invasive ventilation before induction or BMV after induction, fluid bolus administration appeared to decrease the incidence of cardiovascular collapse compared with no fluid bolus (figure 3). For patients not receiving positive pressure ventilation, administration of a fluid bolus appeared to increase the incidence of cardiovascular collapse.

Among the 201 patients co-enrolled in a randomised trial comparing prophylactic BMV between induction and laryngoscopy with no ventilation, fewer patients randomly assigned to BMV appeared to have cardiovascular collapse when also randomised to fluid bolus administration, whereas patients randomly assigned to no BMV appeared to have cardiovascular collapse when randomly assigned to no fluid bolus administration ($p_{\text{interaction}}=0.011$; figure 3).

Discussion

During tracheal intubation of critically ill adults, the risk of cardiovascular collapse might be increased owing to hypovolaemia, impaired systemic vascular resistance, receipt of sedative medications, and reduced venous return from positive pressure ventilation—all of which are potentially amenable to prevention by administration of an intravenous fluid bolus.^{19–24} Our multicentre randomised trial, however, found that administration of a fluid bolus did not affect the overall incidence of cardiovascular collapse during intubation of critically ill adults, compared with no fluid bolus administration.

There are several potential explanations for these findings. First, the recommended and commonly used^{7,16} volume of 500 mL of crystalloid might have been inadequate to influence patient haemodynamics during intubation. Second, the timing of fluid bolus administration beginning before induction and infusing through induction and laryngoscopy might have produced different results than if the full bolus had been administered before induction. Third, administration of a fluid bolus might simply not improve haemodynamics for all patients undergoing intubation in the ICU. Published data suggest that in the days after ICU admission most patients do not show an increase in cardiac output in response to administration of a fluid bolus.²⁵

Fourth, administration of a fluid bolus might have had differential effects for patients with different peri-intubation physiology. Specifically, we found that among patients receiving positive pressure ventilation before induction, either via non-invasive ventilation for pre-oxygenation or bag-mask ventilation between induction and laryngoscopy, administration of a fluid bolus appeared to decrease the risk of cardiovascular collapse.

Figure 2: Cardiovascular collapse in the fluid bolus vs no fluid bolus groups

Horizontal bars represent the overall incidence of the primary outcome in each group. The p value represents the test for a difference between groups in the overall incidence of the primary outcome. Number (%) of patients is given above each bar. SBP=systolic blood pressure.

By contrast, among patients not receiving positive pressure ventilation, including those receiving oxygenation with a high-flow nasal cannula, administration of a fluid bolus appeared to increase the risk of cardiovascular collapse.

Fluid bolus administration might attenuate the decrease in venous return associated with pre-intubation positive pressure ventilation among patients receiving non-invasive ventilation for pre-oxygenation or BMV between induction and laryngoscopy. The only previous study³ to evaluate fluid bolus administration during intubation in the ICU was a before-and-after study of a ten-item pre-intubation checklist, in which cardiovascular collapse occurred less often in the intervention group. In this study, all patients in the intervention group received both non-invasive positive pressure ventilation for pre-oxygenation and a fluid bolus. These findings are consistent with the effect of fluid bolus administration on cardiovascular collapse observed among the subgroup of patients receiving pre-intubation positive pressure ventilation in our trial.

For patients in our trial not receiving positive pressure ventilation, fluid bolus administration appeared to increase the risk of cardiovascular collapse. Several studies have reported a decrease in blood pressure and cardiac output with fluid bolus administration, especially with rapid infusion of the bolus^{10,26,27} as was used in the current trial and during general anesthesia.¹¹ Potential mechanisms by which fluid bolus administration might cause cardiovascular collapse include dilution of endogenous catecholamines,²⁶ stimulation of atrial natriuretic peptide release, and damage to the glycocalyx.^{10,27} Alternatively, the absence of positive

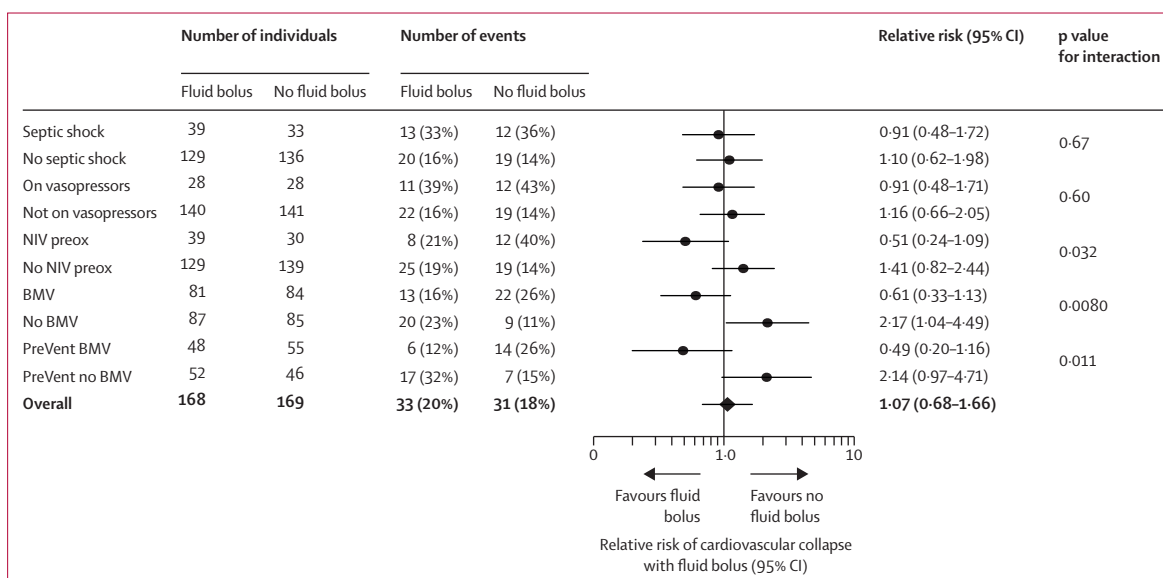

Figure 3: Risk of cardiovascular collapse by subgroup for patients receiving fluid bolus administration vs no fluid bolus administration

On vasopressors refers to patients who were receiving vasopressor infusions any time in the 6 h before enrolment. NIV preox=non-invasive positive pressure ventilation for pre-oxygenation. BMV=bag-mask ventilation to ventilate or oxygenate the patient during the tracheal intubation procedure in all patients enrolled in the trial. PreVent BMV=randomisation assignments in the 201 patients who were co-enrolled in a separate randomised trial of prophylactic vs no prophylactic bag-mask ventilation.

intervention improve generalisability. Protocol compliance was high, with only five patients (1%) receiving the non-assigned therapy. The composite outcome of cardiovascular collapse has been used in other studies of intubation^{3,18} and was strongly associated with patient-centred outcomes in the current study.

The current trial also has limitations. Absence of blinding could have influenced the non-protocolised use of vasopressors or differences in co-interventions; however, we found no significant differences between groups regarding laryngoscope selection, medication selection or doses, or operator experience. The incidence of the primary outcome was lower than previous studies, possibly owing to 17% of patients screened being excluded for a physician-established volume status precluding random assignment, which limits the power of this trial to make inferences about the absence of an effect of a fluid bolus on the incidence of cardiovascular collapse. The trial was stopped early by the DSMB at the planned interim analysis for futility of the intervention among all enrolled patients. This lower-than-planned sample size limits power to exclude an effect of a fluid bolus in patient subgroups with

non-significant interactions. The possibility of positive-pressure ventilation modifying the effect of a fluid bolus on cardiovascular collapse should be considered hypothesis-generating as this subgroup analysis could also be a result of type I error. This multicentre trial was done in eight ICUs and one emergency department with varied patient populations. Although this heterogeneity might increase the external validity of the results, it might also limit the ability to discern the effect of a fluid bolus on cardiovascular collapse in a more homogenous critically ill population. The volume of intravenous fluids that patients received before enrolment was not recorded, therefore it is unknown if this covariate was balanced between groups. Finally, the only protocol requirement was to begin the fluid bolus at any time before the administration of procedural medications, a practice described in past observational studies.^{3,15,16} It is not known whether the results of the trial would have differed if the trial had required the entire volume of the fluid bolus to be infused before induction.

Our findings do not support routine administration of a fluid bolus before induction among patients not

receiving positive pressure ventilation. Given the beneficial effects of BMV during intubation seen in the PreVent trial,¹⁷ future research should examine the hypothesis-generating effect modification seen in the current trial regarding whether fluid bolus administration prevents cardiovascular collapse among patients receiving pre-intubation positive pressure ventilation.

Contributors

DRJ, JDC, MWS, and TWR were responsible for the study concept and design. DRJ, JDC, MWS, DWR, JD, DJV, KMD, JRW, SS, JW, NC, ANZ, SG, WSS, IB, AMJ, and BEH were responsible for acquisition of the data. DRJ, JDC, MWS, and TWR, were responsible for data analysis and interpretation. DRJ, JDC, MWS, and TWR were responsible for manuscript preparation and drafting. DRJ, JDC, MWS, and TWR were responsible for the statistical methods and statistical data analysis. DRJ, JDC, MWS, and TWR were responsible for manuscript critique and review. All authors approved the manuscript submitted. DRJ, JDC, MWS, and TWR take responsibility for the integrity of the work as a whole, had full access to the data, and had final responsibility for the decision to submit for publication. No portion of this work has been previously presented.

Declaration of interests

TWR reported serving on an advisory board for Avisa Pharma, as a Data and Safety Monitoring Board member for Takeda, and Director of Medical Affairs for Cumberland Pharmaceuticals. during the conduct of the study. All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Investigators doing this study were supported by a National Heart, Lung, and Blood Institute (NHLBI) T32 award (HL087738 to JDC and HL105346-07 to DWR). MWS was supported in part by the National Heart, Lung, and Blood Institute (K23HL143053). Data collection used the Research Electronic Data Capture (REDCap) tool developed and maintained with Vanderbilt Institute for Clinical and Translational Research grant support (UL1 TR000445 from NCATS/NIH). All remaining authors declare no competing interests.

Data sharing

Following publication and upon reasonable request, a completely de-identified dataset and data dictionary with individual participant data may be provided by the authors. Request to share data from the PrePARE trial should be sent, along with a brief research proposal, to the corresponding author. The dataset will be provided to researchers whose proposed use of the data has been approved by the steering committee and an Institutional Review Board.

Acknowledgments

The authors thank the patients, nurses, respiratory therapists, residents, fellows, advanced practice providers, and attending physicians of the participating intensive care units.
